

Exam 2016 - solution

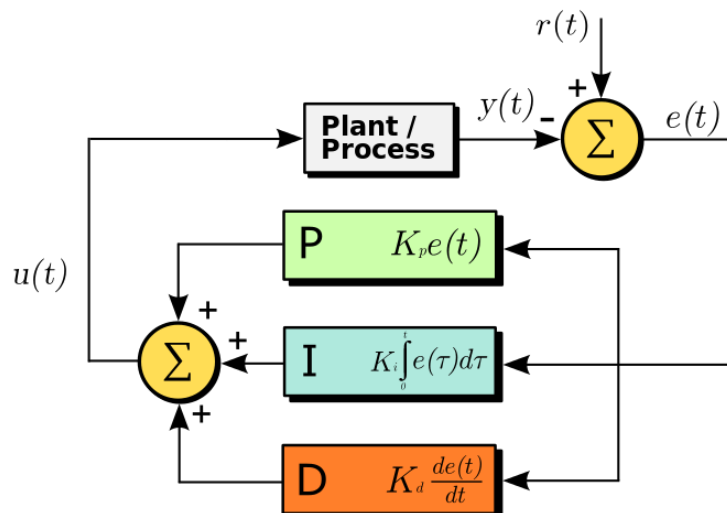

Problem 1

- DC-balance** (equal number of '0' and '1' to get zero offset) and **clock recovery** (Need transitions between '0' and '1' to recover the clock).
- The data and clock are combined into one signal, so that the receiver can recover the transmitter clock (self-clocking). XOR of data and clock gives at least one transition for each clock period; '1' is a low to high transition and '0' is a high to low transition.
- Detect the rising and falling edges of the Manchester encoded signal, but ignore the rising/falling edges with a smaller separation than one clock period (should only get one level transition pr. clock period).

- A controller that switches between two states; e.g. either completely on or completely off. Examples: residential thermostats.
- A PID controller continuously calculates an *error value* $e(t)$ as the difference between a measured process variable $y(t)$ and a desired set point $r(t)$. The controller attempts to minimize the error over time, by adjustment of a *control variable* $u(t)$, such as the position of a control valve.

$$u(t) = K_p e(t) + K_i \int_0^t e(t) dt + K_d \frac{de(t)}{dt}$$

P accounts for present values of the error, I accounts for past values of the error, accumulates over time, and D accounts for possible future values of the error, based on its current rate of change. Must tune the coefficients K_p , K_i og K_d

- f) Filtering uses all past measurements (up to the time t_n of interest), while a smoothing makes use of data both before and after any given time point t_n of interest.

g)

Alpha filter – a first-order approach

- If you have a measurement \tilde{x}_k , you can apply a first order filter:

$$\hat{x}_k = (1 - \alpha)\bar{x}_k + \alpha\tilde{x}_k$$

- \hat{x}_k is the updated (from measurements) estimate at time k
- \bar{x}_k is the predicted (time propagated) estimate at time k , from a **model**:
 $\bar{x}_k = f(\hat{x}_{k-1})$
 - Data fusion example: rate gyro measurement used for predicting a rotation angle and an accelerometer used as an inclinometer to measure the absolute angle.
- α is a scalar gain between 0 and 1 (typically constant)
- If no measurements \tilde{x}_k are available, α is set to 0 \rightarrow only prediction
- This approach will filter out noise, but a good α **must be found from "trial and error"** (possibly with some "guidelines")
- Not as good as a Kalman filter!
 - Not an optimal solution!

Problem 2

- a) Explain determinism! Hard and soft real-time (Deadline, average time, worst-case time).

- b) DAQ-systems. Buffers used in different parts of the system (FIFO buffer on DAQ-card, PC-buffer/Circular buffer in PC RAM, and queues between different loops/threads).
- c) A device driver (from national Instruments), to communicate with DAQ equipment.
- d) Not continuous sampling e.g. due to insufficient use of memory (FIFO and circular buffer to compensate for non-real time behavior of the PC), or due to a busy CPU (DMA not used).
- e) High data bandwidth and high power/current.
- f) For an ideal ADC we can assume an SNR of about $6 \cdot N$, where N is the number of bits. For 16 bits this gives a SNR of about 96 dB. This means that the stop band of our filter should be at about -96 dB at 15 kHz. With a sufficiently high filter order this means that the filter cut-off frequency (at -3 dB) can be set at 5 kHz (or above), to give a filter passband from 0 Hz and up to 5 kHz (or higher).
- g) Two different architectures for handling memory storage. A big-endian machine stores the most significant byte first, at the lowest byte address. A little-endian machine stores the least significant byte first (at the lowest byte address).
- h) A binary file format from National Instruments that is optimized for high-speed streaming.

Problem 3

a)

Computer clocks

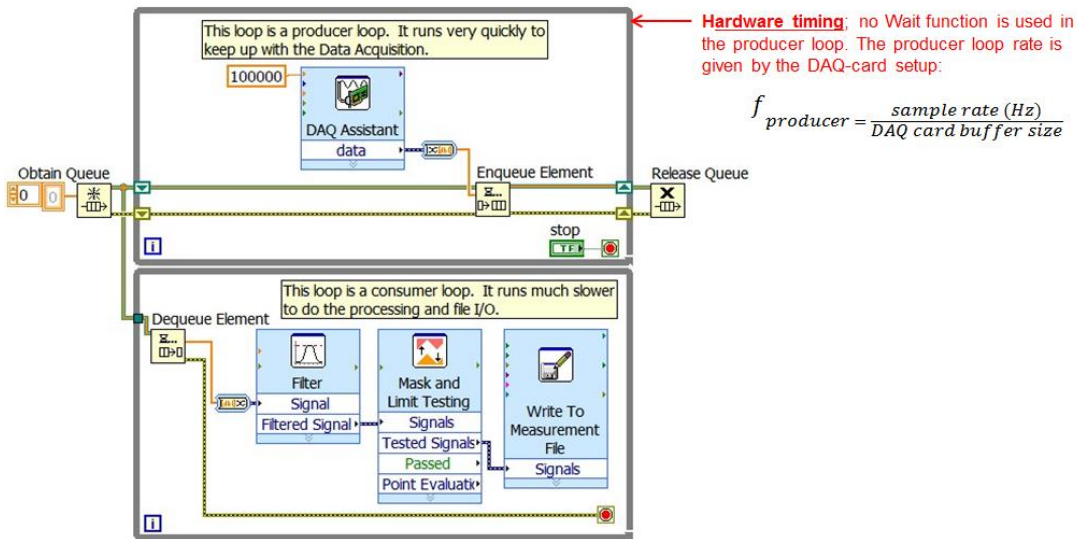

- Hardware clocks
 - **Real Time Clock (RTC)** is an integrated circuit on the motherboard.
 - The RTC has a battery backup power so that it tracks the time even while the computer is turned off.
 - Based on a 32.768 kHz quartz crystal oscillator.
 - Maximum resolution of 1 millisecond (1 kHz).
- Software clocks
 - Maintained by the operating system, based on the RTC interrupts.
 - When the system starts it sets the system time to a value based on the real-time clock of the computer and then regularly updates the time based on interrupts from the RTC.

Timing

- b) Temperature compensation (TCXO) and temperature stabilization (OCXO).

c) Leap seconds added to UTC

d) Hardware timing: A hardware device is in control of the timing; e.g. the sample rate of a DAQ-card is controlled by the onboard DAQ-card oscillator (or a function generator, or a sensor/camera etc.)

Software timing: A wait function is used inside a software loop, using the operating system (software) clock to control the timing of a computer program:
