

IN2110: Språkteknologiske metoder

Klassifikasjon

Erik Velldal

Språkteknologigruppen (LTG)

29. Januar, 2019

- ▶ General approach to representing data in a geometrical model.
- ▶ Example use case: vector spaces for **IR**.
- ▶ Documents represented as points/vectors in a **feature space**, $\mathbf{x} = \langle x_1, \dots, x_n \rangle \in \mathbb{R}^n$.
- ▶ **Bag-of-words**:
 - ▶ **Documents** represented by their unordered collection of word types.
 - ▶ Each **dimension** in the space corresponds to a word in the vocabulary.
- ▶ **Similarity** modeled by **distance** of documents (and queries) in the space.

Recap: measuring similarity

- ▶ **Euclidean** distance between points.
- ▶ **Cosine** similarity of vector angles.
- ▶ Raw counts often weighted by **TF-IDF**.
- ▶ Can reduce length bias by **normalization**.

Today

- ▶ **Classification**: supervised learning
- ▶ Rocchio
- ▶ k NN
- ▶ Representing classes and membership

Next lecture

- ▶ **Clustering**: *unsupervised* learning
- ▶ c -Means

- ▶ Topic classification of news articles
- ▶ Authorship attribution
- ▶ Spam detection
- ▶ Polarity classification (sentiment analysis)
- ▶ Language identification
- ▶ Abusive language detection
- ▶ Question type classification
- ▶ Content recommendation
- ▶ Political affiliation
- ▶ ...

- ▶ In our vector space model, **objects** are represented as **points**, so **classes** will correspond to collections of points; **regions**.

- ▶ Vector space classification is based on **the contiguity hypothesis**:

- ▶ Objects in the same class form a contiguous region, and regions of different classes do not overlap.
- ▶ Classification amounts to computing the boundaries in the space that separate the classes; **the decision boundaries**.
- ▶ How we draw the boundaries is influenced by how we choose to represent the classes.

Exemplar-based

- ▶ No abstraction. Every stored instance of a group can potentially represent the class.
- ▶ Used in so-called *instance based* or *memory based learning* (MBL).
- ▶ In its simplest form; the class = the collection of points.

Exemplar-based

- ▶ No abstraction. Every stored instance of a group can potentially represent the class.
- ▶ Used in so-called *instance based* or *memory based learning* (MBL).
- ▶ In its simplest form; the class = the collection of points.
- ▶ Another variant is to use *medoids*, – representing a class by a single member that is considered central, typically the object with maximum average similarity to other objects in the group.

Exemplar-based

- ▶ No abstraction. Every stored instance of a group can potentially represent the class.
- ▶ Used in so-called *instance based* or *memory based learning* (MBL).
- ▶ In its simplest form; the class = the collection of points.
- ▶ Another variant is to use *medoids*, – representing a class by a single member that is considered central, typically the object with maximum average similarity to other objects in the group.

Centroid-based

- ▶ The average, or the *center of mass* in the region.
- ▶ Given a class c_i , where each object o_j being a member is represented as a feature vector \mathbf{x}_j , we can compute the class **centroid** μ_i as

$$\mu_i = \frac{1}{|c_i|} \sum_{\mathbf{x}_j \in c_i} \mathbf{x}_j$$

Some more notes on centroids, medoids and typicality

- ▶ Both *centroids* and *medoids* represent a group by a single **prototype**.
- ▶ But while a *medoid* is an actual member of the group, a *centroid* is an *abstract* prototype; an average.
- ▶ **Typicality** can be defined by a member's distance to the prototype.
- ▶ The centroid could also be **distance weighted**:
Let each member's contribution to the average be determined by its average pairwise similarity to the other members of the group.
- ▶ There are parallel discussions on how to represent classes and determine typicality within linguistic and psychological prototype theory.

- ▶ AKA **nearest centroid classifier** or nearest prototype classifier.
- ▶ Uses centroids to represent classes.
- ▶ Each class c_i is represented by its **centroid** μ_i , computed as the average of the vectors \mathbf{x}_j of its members;

$$\mu_i = \frac{1}{|c_i|} \sum_{\mathbf{x}_j \in c_i} \mathbf{x}_j$$

- ▶ AKA **nearest centroid classifier** or nearest prototype classifier.
- ▶ Uses centroids to represent classes.
- ▶ Each class c_i is represented by its **centroid** μ_i , computed as the average of the vectors x_j of its members;

$$\mu_i = \frac{1}{|c_i|} \sum_{x_j \in c_i} x_j$$

- ▶ The Rocchio **decision rule**:
- ▶ To classify a new object o_j (represented by a feature vector x_j);
 - determine which centroid μ_i that x_j is closest to,
 - and assign it to the corresponding class c_i .

- ▶ AKA **nearest centroid classifier** or nearest prototype classifier.
- ▶ Uses centroids to represent classes.
- ▶ Each class c_i is represented by its **centroid** μ_i , computed as the average of the vectors x_j of its members;

$$\mu_i = \frac{1}{|c_i|} \sum_{x_j \in c_i} x_j$$

- ▶ The Rocchio **decision rule**:
- ▶ To classify a new object o_j (represented by a feature vector x_j);
 - determine which centroid μ_i that x_j is closest to,
 - and assign it to the corresponding class c_i .

The decision boundary of the Rocchio classifier

- ▶ Defines the boundary between two classes by **the set of points equidistant from the centroids**.
- ▶ In two dimensions, this set of points corresponds to a **line**.
- ▶ In multiple dimensions: A line in 2D corresponds to a **hyperplane** in a higher-dimensional space.
- ▶ The boundaries are not explicitly computed; implied by the decision rule.

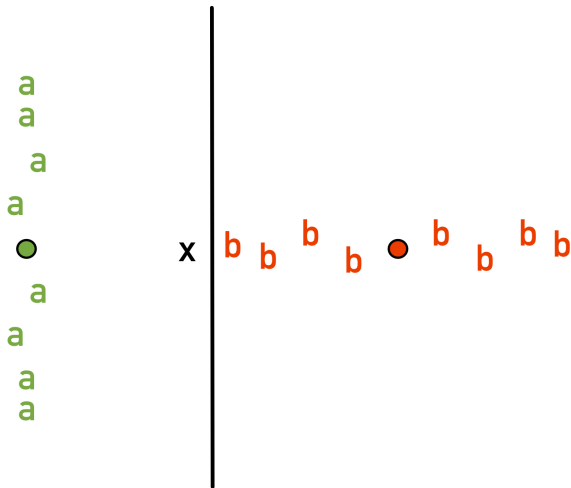

- ▶ The classification decision **ignores the distribution of members** locally within a class, only based on the centroid distance.
- ▶ Implicitly assumes that classes are **spheres** with **similar radii**.
- ▶ Does not work well for classes that cannot be accurately represented by a single prototype or center (e.g. disconnected or elongated regions).
- ▶ Because the Rocchio classifier defines a **linear decision boundary**, it is only suitable for problems involving *linearly separable* classes.

Problematic: Elongated regions

Problematic: Non-contiguous regions

Problematic: Different sizes

Problematic: Nonlinear boundary

- ▶ Before we turn to talk about non-linear classifiers, note that:
Classes that are not linearly separable in a given feature space. . .

- ▶ ... may become linearly separable when the features are mapped to a higher-dimensional space (this is the basis for so-called **kernel** methods).

- ▶ k Nearest Neighbor classification.
- ▶ An example of a memory-based, non-linear classifier.

Decision rule

- ▶ For $k = 1$: Assign each object to the class of its closest neighbor.
- ▶ For $k > 1$: Assign each object to the majority class among its k closest neighbors.
- ▶ The parameter k must be specified in advance.

- ▶ k Nearest Neighbor classification.
- ▶ An example of a memory-based, **non-linear** classifier.

Decision rule

- ▶ For $k = 1$: Assign each object to the class of its closest neighbor.
- ▶ For $k > 1$: Assign each object to the majority class among its k closest neighbors.

- ▶ The parameter k must be specified in advance.
- ▶ Rationale: given *the contiguity hypothesis*, we expect a test object o_i to have the same label as the training objects in the local region of x_i .
- ▶ Unlike Rocchio, the k NN decision boundary is determined locally.
 - ▶ The decision boundary defined by the Voronoi tessellation.

- ▶ Assuming $k = 1$: For a given set of objects in the space, let each object define a cell consisting of all points that are closer to that object than to other objects.
- ▶ Results in a set of convex polygons; so-called **Voronoi cells**.
- ▶ Decomposing a space into such cells gives us the so-called **Voronoi tessellation**.
- ▶ In the general case of $k \geq 1$, the Voronoi cells are given by the regions in the space for which the set of k nearest neighbors is the same.

Decision boundary for 1NN: defined along the regions of Voronoi cells for the objects in each class. Shows the **non-linearity** of k NN.

The effect of K

1-Nearest Neighbor Classifier

15-Nearest Neighbor Classifier

Figures from Elements of Statistical Learning

- ▶ What would happen if $K = N$?

A probabilistic version

- ▶ The probability of membership in a class c given by the proportion of the k nearest neighbors in c .

A probabilistic version

- ▶ The probability of membership in a class c given by the proportion of the k nearest neighbors in c .

Distance weighted votes

- ▶ The score for a given class c_i can be computed as

$$\text{score}(c_i, o_j) = \sum_{\mathbf{x}_n \in \text{knn}(\mathbf{x}_j)} \mathbf{I}(c_i, \mathbf{x}_n) \text{sim}(\mathbf{x}_n, \mathbf{x}_j)$$

where $\text{knn}(\mathbf{x}_j)$ is the set of k nearest neighbors of \mathbf{x}_j , sim is the similarity measure, and $\mathbf{I}(c_i, \mathbf{x}_n)$ is 1 if $\mathbf{x}_n \in c_i$ and 0 otherwise.

- ▶ Can give more accurate results, and also help resolve ties.

- ▶ Not really any *learning* or estimation going on at all;
- ▶ simply **memorizes** all training examples.
- ▶ Generally with ML; the more training data the better.
- ▶ But for k NN, large training sets come with an efficiency penalty.
- ▶ **Test time** is linear in the size of the training set,
- ▶ but independent of the number of classes.
- ▶ A potential advantage for problems with many classes.
- ▶ Notice the similarity to the problem of ad hoc **retrieval** (e.g., returning relevant documents for a given query);
 - ▶ Both are instances of finding nearest neighbors.

- ▶ To **evaluate** a classifier, we measure its number of correct classification predictions on unseen test items.
- ▶ Labeled test data is sometimes referred to as the **gold standard**.
- ▶ We evaluate by comparing the predictions made by the model towards the gold labels.
- ▶ We will consider different **evaluation metrics**,
- ▶ and the different **data splits**: Training, development, and test sets.
- ▶ (Why can't we test on the training data?)

Using data splits

- ▶ While tuning our model, estimated from the **training** set, we repeatedly evaluate towards the **development** or **validation** data.
- ▶ Or, if we have little data, by **n -fold cross-validation**.
- ▶ Then we want to evaluate how well our *final* model *generalizes* on a **held-out test set**.

Example: Evaluating classifier decisions

- Predictions for a given class can be wrong or correct in two ways:

| | gold = positive | gold = negative |
|-----------------------|---------------------|---------------------|
| prediction = positive | true positive (TP) | false positive (FP) |
| prediction = negative | false negative (FN) | true negative (TN) |

Example: Evaluating classifier decisions

- Predictions for a given class can be wrong or correct in two ways:

| |
|-----------------------|
| prediction = positive |
| prediction = negative |

| gold = positive | gold = negative |
|-----------------|-----------------|
|-----------------|-----------------|

| |
|--------------------|
| true positive (TP) |
|--------------------|

| |
|---------------------|
| false negative (FN) |
|---------------------|

| |
|---------------------|
| false positive (FP) |
|---------------------|

| |
|--------------------|
| true negative (TN) |
|--------------------|

Example: Evaluating classifier decisions

$$\text{Accuracy} = \frac{TP+TN}{N}$$

Example: Evaluating classifier decisions

$$\begin{aligned} \text{Accuracy} &= \frac{TP+TN}{N} \\ &= \frac{1+6}{10} = 0.7 \end{aligned}$$

Example: Evaluating classifier decisions

$$\text{Accuracy} = \frac{TP+TN}{N}$$
$$= \frac{1+6}{10} = 0.7$$

$$\text{Precision} = \frac{TP}{TP+FP}$$

$$\text{Recall} = \frac{TP}{TP+FN}$$

Example: Evaluating classifier decisions

$$\begin{aligned}\text{Accuracy} &= \frac{TP+TN}{N} \\ &= \frac{1+6}{10} = 0.7\end{aligned}$$

$$\begin{aligned}\text{Precision} &= \frac{TP}{TP+FP} \\ &= \frac{1}{1+1} = 0.5\end{aligned}$$

$$\begin{aligned}\text{Recall} &= \frac{TP}{TP+FN} \\ &= \frac{1}{1+2} = 0.33\end{aligned}$$

Example: Evaluating classifier decisions

$$\begin{aligned}\text{Accuracy} &= \frac{TP+TN}{N} \\ &= \frac{1+6}{10} = 0.7\end{aligned}$$

$$\begin{aligned}\text{Precision} &= \frac{TP}{TP+FP} \\ &= \frac{1}{1+1} = 0.5\end{aligned}$$

$$\begin{aligned}\text{Recall} &= \frac{TP}{TP+FN} \\ &= \frac{1}{1+2} = 0.33\end{aligned}$$

$$\begin{aligned}\text{F-score} \\ &= 2 \times \frac{\text{precision} \times \text{recall}}{\text{precision} + \text{recall}} = 0.4\end{aligned}$$

- ▶ **Accuracy** = $\frac{TP+TN}{N} = \frac{TP+TN}{TP+TN+FP+FN}$
 - ▶ The ratio of correct predictions.
 - ▶ Not suitable for unbalanced numbers of positive / negative examples.
- ▶ **Precision** = $\frac{TP}{TP+FP}$
 - ▶ The number of detected class members that were correct.
- ▶ **Recall** = $\frac{TP}{TP+FN}$
 - ▶ The number of actual class members that were detected.
 - ▶ Trade-off: Positive predictions for all examples would give 100% recall but (typically) terrible precision.
- ▶ **F-score** = $2 \times \frac{\textit{precision} \times \textit{recall}}{\textit{precision} + \textit{recall}}$
 - ▶ Balanced measure of precision and recall (harmonic mean).

Macro-averaging

- ▶ Sum precision and recall for each class, and then compute global averages of these.
- ▶ The **macro** average will be highly influenced by the **small** classes.

Macro-averaging

- ▶ Sum precision and recall for each class, and then compute global averages of these.
- ▶ The **macro** average will be highly influenced by the **small** classes.

Micro-averaging

- ▶ Sum TPs, FPs, and FNs for all points/objects across all classes, and then compute global precision and recall.
- ▶ The **micro** average will be highly influenced by the **large** classes.

- ▶ Unsupervised machine learning for class discovery: **Clustering**
- ▶ Flat vs. hierarchical clustering.
- ▶ C-Means Clustering.
- ▶ Reading: *Manning, Raghavan & Schütze (2008)*, section 16, 16.1, 16.2, and 16.4 up until 16.4.1.
